GROUND WATER RESOURCES

Louisa County

Open File Report 80-58 WRD
Compiled by Donivan L. Gordon
GROUND-WATER RESOURCES OF LOUISA COUNTY

Introduction

Approximately 96 percent of the water used in Louisa County is drawn from ground water sources. It is estimated that the use of ground water in the county currently approaches 0.6 billion gallons per year. For comparison, this amount would provide each county resident with 177 gallons of water a day during a year. Actually, few if any households use this much water, and the rather large annual per capita use reflects the greater water requirements of the county's industries, agribusinesses, and municipalities.

The users of ground water in the county draw their supplies from several different geologic sources. Several factors must be considered in determining the availability of ground water and the adequacy of a supply source:

- **distribution** - having water where it is needed,
- **accessibility** - affects the costs for drilling wells and pumping water,
- **yield** - relates to the magnitude of the supply that can be sustained,
- **quality** - determines for what purposes the water can be used.

In terms of these factors, there are few locations in Louisa County where the availability of ground water is not limited to some degree. The most common limitation is poor water quality, that is, mineralized ground water. Secondary limitations are generally related to distribution, small yields from some sources, and poor accessibility due to the depth to adequate sources.

Occurrence of Ground Water in Louisa County

The occurrence of ground water is influenced by geology -- the position and thickness of the rock units, their ability to store and transmit water, and their physical and chemical make-up. Geologic units that store and transmit water and yield appreciable amounts to wells are called aquifers. The best aquifers are usually composed of unconsolidated sand and gravel, porous sandstone, and porous or fractured limestone and dolomite. Other units with materials such as clay and silt, shale, siltstone, and mudstone yield little or no water to wells. These impermeable units are called aquicludes or aquitards and commonly separate one aquifer unit from another.
In Louisa County there are four principal aquifers from which users obtain water supplies. The loose, unconsolidated materials near the land surface comprise the surficial aquifer. Below this there are three major rock aquifers -- the Mississippian aquifer, the Devonian aquifer, and the Cambro-Ordovician aquifer. Figure 1 shows the geologic relations of these beneath the county. Each of the aquifers has its own set of geologic, hydrologic, and water quality characteristics which determine the amount and potability (suitability for drinking) of water it will yield.

**Surficial Aquifers**

Unconsolidated deposits at the land surface are comprised of mixtures of clay, silt, sand, gravel, and assorted boulders. The water-yielding potential of the surficial deposits is greatest in units composed mostly of sand and/or gravel. Three types of surficial aquifers are used: the alluvial aquifer, the drift aquifer, and the buried channel aquifer.

The alluvial aquifer consists mainly of the sand and gravel transported and deposited by modern streams and makes up the floodplains and terraces in major valleys. Alluvial deposits are shallow, generally less than 50-60 feet and may be contaminated by percolating surface water.

The drift aquifer is the thick layer of soils materials deposited over the bedrock by glacial ice which invaded the county at least twice in the last two million years. The composition of the glacial drift varies considerably, and where it is silty and clayey it does not yield much water. Locally there are lenses or beds of sand and gravel within the drift which are thick and widespread enough to serve as dependable water sources. These lenses are difficult to locate because they are irregular in shape and buried within the drift deposits. Usually one or two sand layers can be found in most places that will yield enough water for domestic needs.

Buried channel aquifers consist of stream alluvium that partially fills valleys that existed before the glacial period. The valleys, overridden by glaciers, are now buried under glacial and more recent alluvial deposits.

The distribution, yield, and water quality characteristics for the surficial aquifers are summarized in Figures 2, 9, and 13. An indication of aquifer depths can be obtained by comparing the elevations of the top (the land surface) and the bottom (the bedrock surface) of the surficial deposits from Figures 4 and 5. The thickness of the glacial drift and the depth of the buried channels are determined by subtracting bedrock from land surface elevations at selected locations.

- Glacial Drift
- Shale
- Limestone - Dolostone
- Sandstone - Sand

Figure 1

BLOCK DIAGRAM SHOWING GEOLOGY OF LOUISA COUNTY
Rock Aquifers

Below the surficial materials is a thick sequence of layered rocks formed from deposits of rivers and shallow seas that covered the state within the last 600 million years. The geologic map (Figure 3) shows the geologic units which form the top of this rock sequence. The water-bearing characteristics of these units are shown in Table 1.

Examples of the sequence of rock units encountered in drilling existing wells at various locations in Louisa County are indexed and illustrated in Figure 7 and 8. The geologic unit that supplies ground water and the amount of water yielded to the well are shown next to each of the well logs.

The accessibility of ground water in the rock aquifers depends first on the depth to the aquifer. The deeper a well must be, the greater the cost for well construction and pumping. The depths to and thicknesses of units at specific sites will vary somewhat because of irregularities in the elevation of the land surface and in the elevation of the tops of the underlying rock units. Estimates of depths and thicknesses can be made by comparing Figure 4 with the maps of aquifer elevations in Figures 10, 11, and 12. The range in depth below land surface to the top of the county's principal bedrock aquifers is given for each township in Figure 6.

The second factor which affects accessibility is the level to which the water will rise in the well (the static water level). Since water in the rock aquifers is under artesian pressure, the water rises in the well once it penetrates the aquifer. This rise in water level can reduce the cost of pumping. Average static water levels in Louisa County wells are shown in Figures 10, 11, and 12.

Average yields and water quality characteristics throughout the county for each of the aquifers are also summarized in the maps in Figures 10, 11, 12, 13, 14, and 15.

Water levels in the surficial aquifers are difficult to analyze. Water rises to different levels in wells drilled into alluvial, buried-channel, and drift aquifers. The water table in the drift aquifer generally slopes from high land areas toward the streams and, changes noticeably throughout the year. Levels in drift and buried-channel aquifers respond rapidly to recharge from precipitation. Water levels in the alluvial aquifer fluctuate somewhat in the same way as those in the drift and buried-channel aquifers; however, the main influence on the alluvial aquifer is the stage (level) of the associated streams. Water levels will be high during periods of high stream stage and low during the low-stage periods.

Water levels in the drift aquifers commonly are from 10 to 50 feet below the land surface, and those in the buried-channel aquifer have been reported to be as low as 100 feet below the land surface. The water levels in alluvial wells are from 4 to 20 feet below the flood-plain surface, and the depth to the water surface will be accordingly deeper in wells located on terrace surfaces.

Significance of mineral constituents and physical properties of water

<table>
<thead>
<tr>
<th>Constituent or Property</th>
<th>Maximum Recommended Concentration</th>
<th>Significance</th>
</tr>
</thead>
<tbody>
<tr>
<td>Iron (Fe)</td>
<td>0.3 mg/l</td>
<td>Objectional as it causes red and brown staining of clothing and porcelain. High concentrations affect the color and taste of beverages. Iron is not listed in the following tables, as there are often major differences between reported and actual concentrations. It may be added to water from well casings, pumps, and pipes. The concentration also is affected by micro-organisms. Special sampling and analytical techniques are needed for accurate study.</td>
</tr>
<tr>
<td>Manganese (Mn)</td>
<td>0.05 mg/l</td>
<td>Objectional for the same reason as iron. When both iron and manganese are present, it is recommended that the total concentration not exceed 0.3 mg/l. Micro-organisms also affect the concentration. Special techniques are needed for an accurate study.</td>
</tr>
<tr>
<td>Calcium (Ca) and Magnesium (Mg)</td>
<td></td>
<td>Principal causes for hardness and scale-forming properties of water. They reduce the lathering ability of soap.</td>
</tr>
<tr>
<td>Sodium (Na) and Potassium (K)</td>
<td></td>
<td>Import a salty or brackish taste when combined with chloride. Sodium salts cause foaming in boilers.</td>
</tr>
<tr>
<td>Sulfate (SO₄)</td>
<td>250 mg/l</td>
<td>Commonly has a laxative effect when the concentration is 600 to 1,000 mg/l, particularly when combined with magnesium or sodium. The effect is much less when combined with calcium. This laxative effect is commonly noted by newcomers, but they become accustomed to the water in a short time. The effect is noticeable in almost all persons when concentrations exceed 750 mg/l. Sulfate combined with calcium forms a hard scale in boilers and water heaters.</td>
</tr>
<tr>
<td>Chloride (Cl)</td>
<td>250 mg/l</td>
<td>Large amounts combined with sodium impart a salty taste.</td>
</tr>
<tr>
<td>Fluoride (F)</td>
<td>2.0 mg/l</td>
<td>Concentrations of 0.8 to 1.3 mg/l are considered to play a part in the reduction of tooth decay. However, concentrations over 2.0 mg/l will cause the pitting of the enamel of children’s teeth.</td>
</tr>
<tr>
<td>Nitrates (NO₃)</td>
<td>45 mg/l</td>
<td>Waters with high nitrate content should not be used for infant feeding as it may cause methemoglobinemia or cyanosis. High concentrations suggest organic pollution from sewage, decaying organic matter, nitrate in the soil, or chemical fertilizer. High nitrates in the natural waters of central Iowa are limited to isolated occurrences, usually from shallow dug wells on farms. Since the high concentrations are characteristic of individual wells and not of any one aquifer, nitrate will not be discussed in this report.</td>
</tr>
<tr>
<td>Dissolved Solids</td>
<td>500 mg/l</td>
<td>This refers to all of the material in water that is in solution. It affects the chemical and physical properties of water for many uses. Amounts over 2,000 mg/l will have a laxative effect on most persons. Amounts up to 1,000 mg/l are generally considered acceptable for drinking purposes if no other water is available.</td>
</tr>
<tr>
<td>Hardness (as CaCO₃)</td>
<td></td>
<td>This affects the lathering ability of soap. It is generally produced by calcium and magnesium. Hardness is expressed in parts per million equivalent to CaCO₃ as if all the hardness were caused by this compound. Water becomes objectionable for domestic use when the hardness is above 100 mg/l; however, it can be treated readily by softening.</td>
</tr>
<tr>
<td>Temperature</td>
<td></td>
<td>Affects the desirability and economy of water use, especially for industrial cooling and air conditioning. Most users want a water with a low and constant temperature.</td>
</tr>
<tr>
<td>Suspended Sediment</td>
<td></td>
<td>Causes water to have a cloudy or muddy appearance. It must be settled or filtered out before the water is used. It is the material that “slits-up” reservoirs, and it is the major cause of the reduction of reservoir life.</td>
</tr>
</tbody>
</table>

To the user, the quality of ground water is as important as the amount of water that an aquifer will yield. As ground water moves through soil and rock materials, it dissolves some of the minerals which, in turn, affect water quality. In addition to mineral content, bacterial and chemical contamination may be introduced through poorly constructed wells and seepage from other pollution sources.

Recommended standards for common water constituents are described in the table above. These are nationally accepted as guidelines for acceptable drinking water supplies. Limits for uses other than drinking often differ from these. For instance, water that is unacceptable for drinking and household use may be completely satisfactory for industrial cooling.

From analyses of ground water, averages (A) and ranges (R) of values in milligrams per liter (mg/l) for several mineral constituents are summarized in Figures 13, 14, and 15 for the 4 major aquifers in Louisa County. Recommended concentrations for some constituents are often exceeded without obvious ill effects, although the water may be unpalatable.

Water quality analyses for individual wells should be obtained to determine if concentrations of constituents that affect health are exceeded.
The drift, alluvial, and buried-channel aquifers all yield good quality water. However, dissolved solids concentrations in water from the drift are higher. The water temperature from the three sources average 54°F and normally do not vary by more than 6°F.

Mississippian Aquifer

Water in the upper part of the Mississippian aquifer is comparable to that typically found in the drift aquifer and is usually hard. Sulfate concentrations vary but generally meet recommended standards. Average water temperature is 55°F with a range of 51°-60°.
Water in the lower part of the Mississippian aquifer is generally of good quality. Throughout the county the water is hard, and in most localities meets, does not exceed, recommended standards for sulfate and total dissolved solids and other quality parameters. Average water temperature is 55°F with a range of 51°-60°.
Figure 15
CHEMICAL CHARACTER OF GROUND WATER
Devonian Aquifer

Water in the Devonian aquifer is highly mineralized and objectionally hard except along the eastern margin in the county. Because of extremely high total dissolved solids, primarily sodium-potassium, chloride, and sulfate, the water from the Devonian is unfit for human or animal consumption in a large proportion of the county. The average water temperature is 60°F and ranges between 54° and 64° in southeast Iowa.

Cambro-Ordovician Aquifer

This deep aquifer yields water of relatively poor quality compared to the surficial and Mississippian aquifers. The water is noticeably hard and exceeds recommended standards for sulfate and dissolved solids. Water temperatures are higher than other rock aquifer sources, averaging 72°F and ranging up to about 75°.
RECOMMENDATIONS FOR PRIVATE WATER WELLS

Contracting for Well Construction

To protect your investment and guarantee satisfactory well completion, it is a good idea to have a written agreement with the well driller. The agreement should specify in detail:

- size of well, casing specifications, and types of screen and well seal
- methods of eliminating surface and subsurface contamination
- disinfection procedure to be used
- type of well development if necessary
- test pumping procedure to be used
- date for completion
- itemized cost list including charges for drilling per foot, for materials per unit, and for other operations such as developing and test pumping
- guarantee of materials, workmanship, and that all work will comply with current recommended methods
- liability insurance for owner and driller

Well Location

A well should be located where it will be least subject to contamination from nearby sources of pollution. The Iowa State Department of Health recommends minimum distances between a new well and pollution sources, such as cesspools (150 ft.), septic tanks (50 ft.), and barnyards (50-100 ft. and down slope from well). Greater distances should be provided where possible.

The well location should not be subject to flooding or surface water contamination. Select a well-drained site, extend the well casing a few feet above the ground, and mound earth around it. Diversion terraces or ditches may be necessary on slopes above a well to divert surface runoff around the well site.

In the construction of all wells care should be taken to seal or grout the area between the well bore and the well casing (the annulus) as appropriate so that surface water and other pollutants cannot seep into the well and contaminate the aquifer.
Water Treatment

Water taken from a private well should ideally be tested every six months. The University Hygienic Laboratory will do tests for coliform bacteria, nitrate, iron, hardness, and iron bacteria in drinking water for private individuals. Special bottles must be used for collecting and sending water samples to the laboratory. A sample kit can be obtained by writing to the University Hygienic Laboratory, University of Iowa, Oakdale Campus, Iowa City, Iowa 52242. Indicate whether your water has been treated with chlorine, iodine, or bromine; as different sample bottles must be used for treated and untreated water. The charge for the bacterial test is $3.00; for iron, hardness, and nitrate, it is $3.00; and for iron bacteria, $5.00. If your well is determined to be unsafe, advice for correcting the problem can be obtained from your county or state Department of Health. Several certified private laboratories also run water analyses.

Shock chlorination is recommended following the construction and installation of a well and distribution system and any time these are opened for repairs or remodeling a strong chlorine solution is placed in the well and complete distribution system to kill nuisance and disease-causing organisms. If the first shock chlorination does not rid the water supply of bacteria it should be repeated, if this does not solve the problem the well should be abandoned or the water should be continuously disinfected with proper chlorination equipment.

Since most of the ground waters in Louisa County are mineralized, water softening and iron removal equipment may make water more palatable and pleasant to use. Softened water contains increased sodium; contact your physician before using a softener if you are on a sodium-restricted diet. Chlorination followed by filtration will remove most forms of iron and iron bacteria. Iron bacteria has no adverse effect on health but will plug wells, water lines, and equipment and cause tastes and odors. Iron removal equipment can be used if problems persist.

Well Abandonment

Wells taken out of service provide easy access for pollution to enter aquifers supplying water to other wells in the vicinity. Unprotected wells may also cause personal injury. Proper abandonment procedures should be followed to restore conditions to those that existed before the well was constructed, and to prevent source contamination. Permanent abandonment requires careful sealing. The well should be filled with concrete, cement grout, or sealing clays throughout its entire length. Before dug or bored wells are filled at least the top 10 feet of lining should be removed so surface waters will not penetrate the subsurface through a porous lining or follow cracks in or around the lining. The site should be completely filled and mounded with compacted earth.

ABANDONED WELLS SHOULD NEVER BE USED FOR DISPOSAL OR SEWAGE OR OTHER WASTES.
SOURCES OF ADDITIONAL INFORMATION

In planning the development of a ground water supply or contracting for the drilling of a new well additional or more specific information is often required. This report section lists several sources and types of additional information.
